

# Updates to the ranges of *Psammodromus edwarsianus*, *P. hispanicus*, and *P. occidentalis* in the Iberian Peninsula based on citizen science and new genetic data

Paul Doniol-Valcroze<sup>1,\*</sup>, Philippe Geniez<sup>2</sup>, and Pierre-André Crochet<sup>1</sup>

The genus *Psammodromus* comprises six species of lacertid lizards: *P. microdactylus* (Boettger, 1881) and *P. blanci* (Lataste, 1880) are endemic to North Africa; *P. algirus* (Linnaeus, 1758) is found in North Africa, Iberia, and southern France; *P. edwarsianus* (Dugès, 1829) is found in Iberia and southern France; and *P. occidentalis* Fitze et al., 2012 and *P. hispanicus* Fitzinger, 1826 are only found in Iberia. Of these, *P. edwarsianus*, *P. hispanicus*, and *P. occidentalis* were only recently recognised as distinct species based on genetic, morphological, and ecological niche divergence data (Fitze et al., 2011, 2012).

*Psammodromus edwarsianus* had long been recognised as a valid subspecies of *P. hispanicus* and can easily be differentiated from the two other species by the presence of a supralabial scale that separates its subocular scale from the lip (vs. subocular reaches the lip in the other two species) and other differences in head shape and coloration. Its range has been broadly described (as a subspecies of *P. hispanicus*) to include southern France and the Spanish autonomous communities of Catalonia, Aragon, Valencia, and Murcia (Böhme, 1981), with its southernmost location in Granada Province, Andalusia, added by Fitze et al. (2011; see Faria et al., 2021). However, in spite of these general statements, the range of *P. edwarsianus* remains imperfectly known and, as far as we know, no

attempt has been made to properly map its distribution.

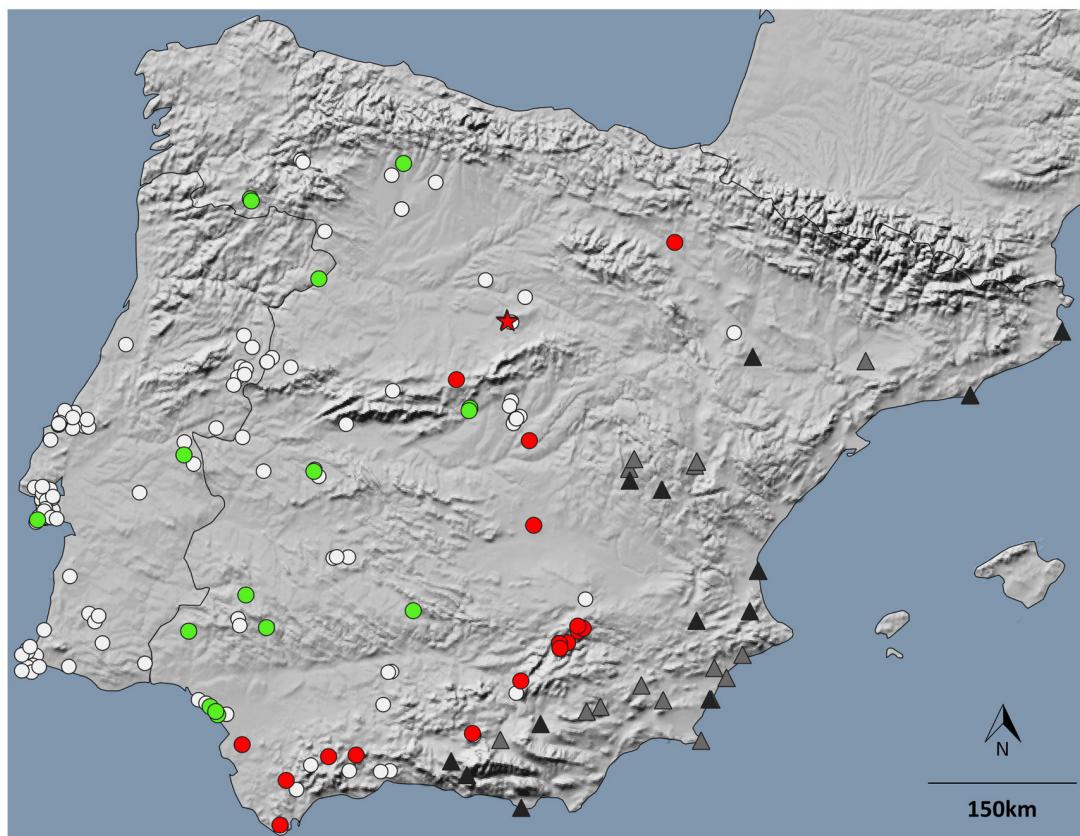

*Psammodromus occidentalis* and *P. hispanicus* are very similar morphologically with no diagnostic features separating the two (Fitze et al., 2011, 2012) and multivariate classification correctly identifies only around 80% of individuals (San-Jose et al., 2012). Safe field identification is thus impossible based on current knowledge, and genetic identification is currently needed to confirm new localities of these two species. Both species occur in the Spanish autonomous communities of Castilla-León, Castilla-La Mancha, Madrid, Extremadura, and Andalusia, in Navarra Province, as well as in Portugal (Böhme, 1981; Fitze, 2012a–c; Faria et al., 2021). Due to difficulties with their identification, very few specific localities have been confirmed for these two species (16 for *P. occidentalis*, 20 for *P. hispanicus*) and their ranges are poorly known as a consequence. It appears although that they are mostly parapatric, with *P. occidentalis* in the west of the range and *P. hispanicus* in the east (Fitze et al., 2011, 2012; Mendes et al., 2017; Molina et al., 2020; Faria et al., 2021; Fig. 1).

We here present an updated range map for these three species (Fig. 1), using data compiled from published localities confirmed using molecular data, images from iNaturalist.org and Observado.org, specimens held in the collection of the Biogéographie et Ecologie des Vertébrés team (BEV) in CEFE (Montpellier), and the photos in the photographic collection of Philippe Geniez (PG). Specimens in the BEV collection or photos in the PG collection (see individual codes in the Appendix) are available from the authors on request. Records based on photos or on specimens for which genetic data were not available were considered to be *P. edwarsianus* if they possessed a supralabial scale below the subocular scale. All other specimens were retained as a single *P. occidentalis/hispanicus* grouping. Photos that did not show this feature clearly were discarded. For *P. edwarsianus*, we only report Spanish localities here because its range in France is already well known (Geniez

**Figure 1.** Ranges of three *Psammodromus* species in the Iberian Peninsula. Symbols represent *P. edwarsianus* (black triangles = genetically confirmed, grey triangles = morphologically confirmed), *P. hispanicus* (red circles = genetically confirmed), *P. occidentalis* (green circles = genetically confirmed), and *P. occidentalis/hispanicus* (white circles = morphologically confirmed). The red star identifies the locality of the new genetically confirmed *P. hispanicus* population.

and Cheylan, 2012). All data used to produce the map are given in the Appendix. Note that many localities on iNaturalist, notably all localities for *P. occidentalis*, are given with imprecise locations (accuracy of 28 km) due to the policy of this database on threatened species (see <https://www.inaturalist.org/pages/help#geoprivacy>). At the scale of the Iberian Peninsula, this only minimally affects the map provided here.

We also present new localities for *P. hispanicus* based on three adult females collected near Carrascal del Rio, Segovia, Spain on 25 May 2016 (41.3647°N, 3.9028°W, WGS84; specimen BEV.14627 / tissue sample T11267) and 26 May 2016 (41.3530°N, 3.8896°W; specimens BEV.14628–29 / tissue samples T11268–69). The first specimen was collected in a grassy clearing between dry open forests and cultivated land. The other specimens were found in a dry, steppe-like habitat on uncultivated slopes of small limestone

hills. The head scalation of these individuals excluded *P. edwarsianus* but, since they were collected close to the known range limits of the two other species (Fig. 1), genetic data were needed to identify them. We therefore barcoded these individuals, assuming that mitochondrial DNA is species-diagnostic in these species, as suggested by previous results, although the lack of cyto-nuclear discordance near contact zones has not been verified (Fitze et al., 2011, 2012).

Total genomic DNA was extracted from tail tips using the Dneasy Blood and Tissue Kit (QIAGEN, Hilden, Germany) following recommended procedures. Negative extraction blanks were made by processing tubes without tissue in exactly the same way as tissue samples and were used in all PCR reactions to ensure a lack of contamination. As an 879 bp fragment of the *ND4* gene was already available for all *Psammodromus* species (Fitze et al., 2011, 2012), this locus was amplified for our samples us-

ing primers ND4F (TTACTTTTACTTGGAGTTGCAC-CA) and ND4R (CACCTATGACTACCAAAAGCT-CATGTAGAAGC; Arévalo et al., 1994). PCR reactions were conducted in 20 µl volumes with 2 µl of DNA, 10 µl of Taq Polymerase [1×] (REDExtract-N-Amp PCR ReadyMix, Sigma-Aldrich, Saint Louis, Missouri, USA), 0.5 µl of each primer [10 µM], and 7 µl of purified water. Amplifications were performed using the following protocol: initiation of 5 min at 94°C; 40 cycles of 95°C for 30 s, 58°C for 1:30 min, 72°C for 1 min; and final elongation of 10 min at 72°C. To test the success of the PCR, 3 µl of PCR product was migrated on a 1% agarose gel for 30 min at 100 V and 80 mA. Successfully amplified DNA fragments were sequenced by Eurofins Genomics (Ebersberg, Germany) using the same primers as for amplification. Sequences have been deposited in GenBank under accession numbers OM974543, OM974544, and OM974545 for specimens BEV.14627, BEV.14628, and BEV.14629, respectively.

The *ND4* sequences from the three samples were compared to reference samples of *P. microdactylus* (MF684964–66), *P. blinci* (MF684968–70), *P. algirus* (FJ587983–85), *P. edwarsianus* (FJ587814–16), *P. occidentalis* (FJ587833–35), and *P. hispanicus* (FJ587823–24, FJ587826). A phylogenetic tree was constructed from the alignment of *ND4* sequences using the Maximum Likelihood algorithm implemented in Mega-X (Kumar et al., 2018) with 1000 bootstraps and the HKY+G substitution model, which was selected as the best-fitting substitution model using defaults settings implemented in Mega-X.

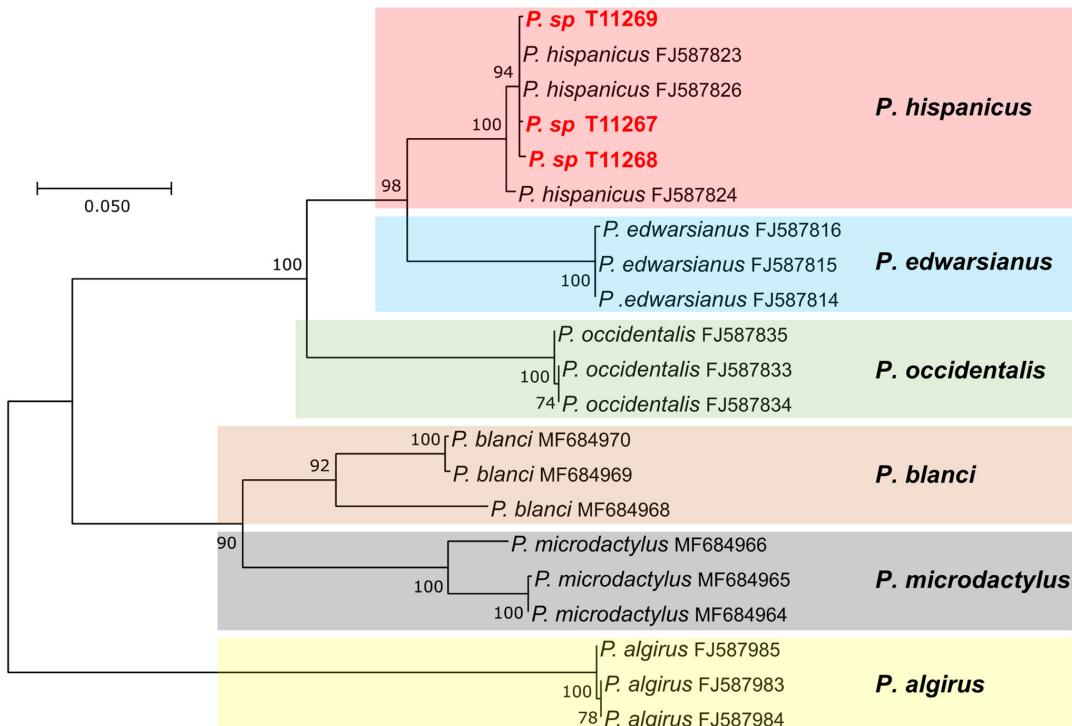

The three individuals from Carrascal del Rio were identified as *P. hispanicus* (Fig. 2) and constitute a new locality for this species (Fig. 1). The two localities are 1.7 km distant (by air) from each other, 85 km and 200 km from the two closest *P. hispanicus* localities at El Espinar and Andosilla, and 103 km and 202 km from the closest *P. occidentalis* localities at Colmenar del Arroyo and Monte León (Fitze et al., 2011, 2012). They constitute the first indication of the occurrence of the species in the plateau of Castilla-Léon north of the Sistema Central mountains. At the northern edge of these plateaux, *P. occidentalis* has been identified just north of León (Fitze et al., 2011, 2012), indicating that these two species must meet somewhere on the northern plateau of Castilla-Léon. The large geographic distance between known *P. hispanicus* and *P. occidentalis* localities illustrates the incomplete knowledge of these species and the need to find and publish new confirmed localities. Genetic identification is currently

the only reliable method to confirm such records, but morphological criteria to separate *P. hispanicus* and *P. occidentalis* should be investigated to assist in determining the exact ranges of these two species.

Our study also helps refine the range limits for *P. edwarsianus* and *P. hispanicus*. Under the assumption that *P. occidentalis* and *P. hispanicus* are entirely parapatric, the range of *P. edwarsianus* only comes close to that of *P. hispanicus* (Fig. 1). Most of our additional, morphology-based localities fall inside the distribution polygons of previous genetic samples, which suggests that populations of the *P. hispanicus* complex are scarce or absent in many areas where information on species identity is currently lacking. In the Ebro depression, a photo of *P. hispanicus/occidentalis* from Zaragoza (iNat/80749918; Appendix) considerably reduces the gap between *P. edwarsianus* and *P. hispanicus* and may indicate the existence of a potential contact zone which could be studied to evaluate the presence and extent of gene flow between *P. edwarsianus* and *P. hispanicus*. Further dedicated fieldwork in the areas between mapped localities (Fig. 1) is necessary to refine the western range limit of *P. edwarsianus* and the eastern range limit of *P. hispanicus*, which can be established by simple visual examination of the specimens.
